gtopt: A Novel High-Performance Tool for Generation and Transmission Expansion Planning

Marcelo Matus A., *Member, IEEE,* María del Pilar Buitrago Villada, Erick Sierra Baeza, Carlos Enrique García Bujanda, Marcos Falcone Salazar, and Gonzalo Bustos Turu

***Abstract*—The increasing penetration of variable renewable energy and the growing complexity of multi-sector energy systems demand planning tools that can co-optimize generation, transmission, and storage investments while capturing detailed operational constraints over long horizons under uncertainty. Existing open-source tools, primarily implemented in Python and Julia, can face computational bottlenecks when assembling sparse LP/MIP problems with millions of variables. This paper presents gtopt, a novel, high-performance Generation and Transmission Expansion Planning (GTEP) tool implemented in modern C++26. The joint investment and operational planning problem is formulated as a sparse linear program over a multi-stage, multi-scenario time hierarchy, supporting DC optimal power flow with Kirchhoff voltage-law constraints, battery energy storage with charge/discharge efficiency modeling, hydro cascade systems with reservoirs and turbines, spinning reserve requirements, water rights and irrigation agreement constraints with volume-dependent dynamic bounds, and capacity expansion with annualized investment costs. Three solution methods are provided: a monolithic LP solver, Stochastic Dual Dynamic Programming (SDDP) with multi-scenario apertures, and a novel multi-level cascade decomposition. Pluggable LP solver backends (CLP, CBC, CPLEX, HiGHS) are loaded at runtime as dynamic libraries. Validation against IEEE benchmark networks (4–57 buses, 13 test cases) and cross-comparison with pandapower DC OPF demonstrate agreement to solver tolerance ($< 10^{-6}$ relative error). Computational experiments show a 10–27$\times$ speedup in sparse-matrix assembly over Python-based alternatives, with the largest test case (57-bus, 8760 blocks, $\sim$18M variables) assembling in approximately 8 seconds.**

***Index Terms*—Generation expansion planning, transmission expansion planning, linear programming, DC optimal power flow, stochastic dual dynamic programming, battery energy storage, hydro cascade, irrigation agreements, water rights, sparse LP assembly.**

I. Introduction

The global energy transition toward low-carbon power systems requires sophisticated planning tools capable of co-optimizing generation, transmission, and storage investments while capturing the operational complexity of variable renewable energy sources and hydro cascades [1]. Generation and Transmission Expansion Planning (GTEP) is the class of optimization problems that determines the minimum-cost combination of infrastructure investments (CAPEX) and dispatch decisions (OPEX) over long planning horizons under uncertainty [2], [3].

Traditional GTEP tools—both commercial (PLEXOS, PLP/PROMAX) and academic—have been implemented in Fortran or commercial modeling languages, limiting accessibility and extensibility. The emergence of open-source alternatives such as PyPSA [4], GenX [5], and IDAES-GTEP [6] has broadened access to planning tools through Python and Julia implementations. However, these interpreted-language tools face computational bottlenecks when assembling large sparse LP/MIP problems with millions of variables and constraints [7]. A tradeoff exists between the accessibility of high-level modeling languages and the computational efficiency required for large-scale stochastic expansion planning with detailed network constraints.

This paper presents gtopt, a novel high-performance GTEP tool implemented in modern C++26 that bridges this gap by combining the computational efficiency of compiled-language sparse-matrix assembly with the accessibility of JSON/Parquet-based data interfaces. gtopt descends from the FESOP (Fabulous Energy System Optimizer) framework [8], which extended long-term hydrothermal scheduling tools [9] to include capacity expansion, variable renewable energy representation, and modern flexibility mechanisms.

The main contributions of this work are:

1) A complete mathematical formulation of the GTEP problem as a sparse LP/MIP, including DC optimal power flow with Kirchhoff constraints, battery storage with charge/discharge efficiencies, hydro cascades with reservoirs and turbines, spinning reserves, a generic water rights layer for irrigation agreement modeling, and multi-stage capacity expansion (Section III).
2) Three solution methods—monolithic LP, SDDP with multi-scenario apertures, and a novel multi-level cascade decomposition—with formal equivalence guarantees (Section IV).
3) A modular software architecture with pluggable solver backends loaded as dynamic libraries, native Apache Parquet I/O, and a comprehensive Python toolchain for data preparation and cross-validation (Section V).
4) Validation against 13 IEEE benchmark cases (4–57 buses) including battery storage and capacity expansion

variants, with cross-validation against pandapower DC OPF demonstrating agreement to solver tolerance (Section VI).

The remainder of this paper is organized as follows. Section II reviews the state of the art in GTEP tools and methods. Section III presents the mathematical formulation. Section IV describes the three solution methods. Section V details the software architecture. Section VI presents validation results on IEEE benchmark networks. Section VIII concludes with a summary and future research directions.

II. Literature Review

A. Generation and Transmission Expansion Planning

GTEP is a classical problem in power systems that has been studied extensively since the 1970s. Romero et al. [10] provided canonical test systems and mathematical models—including transportation, hybrid, DC power flow, and disjunctive formulations—that remain standard benchmarks. Hemmati et al. [2] presented a comprehensive review covering generation expansion planning (GEP), transmission expansion planning (TEP), and their integration. More recently, Mahdavi et al. [3] classified TEP literature into categories by mathematical model, solution method, and uncertainty handling, identifying a trend toward stochastic, multi-objective, and market-based formulations.

Lumbreras and Ramos [1] surveyed modern challenges in TEP including renewable integration, energy storage, and the need for multi-stage stochastic models. These challenges motivate the development of tools that can handle joint generation, transmission, and storage expansion under operational uncertainty.

B. DC Optimal Power Flow

The DC power flow approximation linearizes the AC power flow equations by assuming lossless lines, flat voltage profiles, and small angle differences [11]. Despite its simplifications, DC OPF is the standard formulation for TEP because it yields a linear program amenable to efficient solution [7]. Molzahn and Hiskens [12] provided a comprehensive survey of relaxations and approximations, confirming that DC OPF remains the workhorse for expansion planning despite advances in convex relaxations of AC OPF.

`gtopt` adopts the B-θ formulation (susceptance-angle) for DC OPF, as recommended by Stott et al. [11], with extensions for resistive losses via piecewise-linear approximations and phase-shifting transformers.

C. Stochastic Dual Dynamic Programming

The Stochastic Dual Dynamic Programming (SDDP) algorithm, introduced by Pereira and Pinto [13], is the standard method for solving large-scale multi-stage stochastic programs in hydrothermal scheduling. The algorithm constructs piecewise-linear approximations of the expected cost-to-go function through iterative forward and backward passes.

Shapiro [14] provided theoretical convergence analysis of SDDP, and Philpott and de Matos [15] extended the algorithm with risk-averse sampling. Recent advances include batch learning SDDP [16], which frames the algorithm as Q-learning for improved convergence, and extensions to stochastic OPF under uncertainty [17].

In the Julia ecosystem, Dowson and Kapelevich [18] developed SDDP.jl, a modular SDDP implementation. `gtopt` provides a C++ SDDP implementation with support for multi-scenario apertures, elastic filters for feasibility management, and boundary cost cuts for rolling horizon studies.

D. Energy Storage in Expansion Planning

The integration of battery energy storage systems (BESS) into expansion planning has received significant attention. Go et al. [19] assessed the economic value of co-optimized grid-scale storage investments. Frazier et al. [20] presented an integrated MILP for generation, transmission, and storage expansion with Benders decomposition.

Sandia National Laboratories released QuESt Planning [21], an open-source capacity expansion tool focused on storage, while IDAES-GTEP [6] provides a modular Pyomo-based framework for GTEP. `gtopt` supports BESS with detailed charge/discharge efficiency modeling, state-of-charge tracking across stages, and co-located generation-storage coupling via its converter mechanism.

E. Open-Source Power System Tools

Table I compares `gtopt` with the leading open-source GTEP tools. PyPSA [4] is the most widely adopted, offering multi-sector coupling and a large community, but uses Python for LP assembly which can bottleneck on large problems. GenX [5] provides a flexible Julia/JuMP framework but lacks native DC OPF and hydro cascade modeling. pandapower [22] excels at power flow analysis but does not support expansion planning.

`gtopt` distinguishes itself through: (i) C++ sparse-matrix assembly for high performance, (ii) complete hydro cascade modeling with reservoirs, waterways, turbines, and filtration, (iii) a generic water rights layer for irrigation agreement constraints with volume-dependent dynamic bounds, (iv) three solution methods including SDDP and cascade decomposition, (v) native Apache Parquet I/O for large time-series, and (vi) a comprehensive Python toolchain for data preparation and cross-validation.

III. Mathematical Formulation

A. Sets and Indices

The GTEP problem is defined over the following sets:

- $\mathcal{S}$: scenarios, indexed by s, with probability π_s
- $\mathcal{T}$: stages (planning periods), indexed by t
- $\mathcal{B}_t$: blocks (operating periods) in stage t, indexed by b, with duration Δ_b [h]
- $\mathcal{N}$: buses (electrical nodes), indexed by n
- $\mathcal{G}$: generators, indexed by g, with bus n_g
- $\mathcal{D}$: demands, indexed by d, with bus n_d
- $\mathcal{L}$: transmission lines, indexed by ℓ, connecting buses a_ℓ and b_ℓ

TABLE I: Comparison of Open-Source GTEP and Power System Tools

Feature	gtopt	PyPSA	GenX	IDAES-GTEP	QuESt	PLP
Language	C++26	Python	Julia	Python	Python	Fortran
License	BSD-3	MIT	GPL-2	BSD-3	BSD-3	Proprietary
DC OPF (Kirchhoff)	✓	✓	Transport	✓	–	✓
Hydro cascades	✓	Partial	–	–	–	✓
Battery storage	✓	✓	✓	Partial	✓	Partial
SDDP solver	✓	–	–	–	–	✓

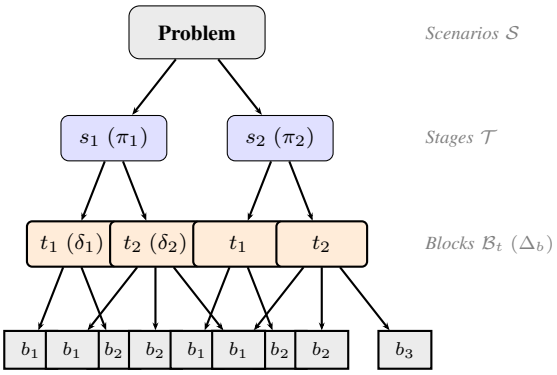

Fig. 1: Three-level time hierarchy. The problem decomposes into scenarios s (probability π_s), stages t (discount factor δ_t), and blocks b (duration Δ_b).

- $\mathcal{E}$: batteries (energy storage), indexed by e
- $\mathcal{V}$: converters (battery↔grid), indexed by v
- $\mathcal{J}$: hydraulic junctions, indexed by j
- $\mathcal{R}$: reservoirs, indexed by r, with junction j_r
- $\mathcal{W}$: waterways, indexed by w
- $\mathcal{H}$: turbines, indexed by h
- $\mathcal{Z}$: reserve zones, indexed by z
- $\mathcal{P}$: reserve provisions, indexed by p
- $\mathcal{FR}$: flow rights (flow-based water rights), indexed by i
- $\mathcal{VR}$: volume rights (volume-based water rights), indexed by o

B. Decision Variables

Operational variables (per scenario s, stage t, block b):

$$p_{g,s,t,b} \in [\underline{p}_g, \overline{p}_g] \quad \text{generator output [MW]} \tag{1}$$

$$\ell_{d,s,t,b} \in [0, \overline{\ell}_d] \quad \text{served demand [MW]} \tag{2}$$

$$q_{d,s,t,b} \geq 0 \quad \text{unserved demand [MW]} \tag{3}$$

$$f_{\ell,s,t,b} \in [-\overline{F}^{ba}_\ell, \overline{F}^{ab}_\ell] \quad \text{line flow [MW]} \tag{4}$$

$$\theta_{n,s,t,b} \in \mathbb{R} \quad \text{voltage angle [rad]} \tag{5}$$

Storage state variables:

$$e_{e,s,t,b} \in [\underline{e}_e, \overline{e}_e] \quad \text{battery SoC [MWh]} \tag{6}$$

$$v_{r,s,t,b} \in [\underline{v}_r, \overline{v}_r] \quad \text{reservoir volume [hm}^3\text{]} \tag{7}$$

Investment variables (per stage t):

$$m_{g,t} \in [0, \overline{m}_g] \quad \text{expansion modules built} \tag{8}$$

C. Objective Function

Minimize total expected discounted cost:

$$\min \sum_{s\in\mathcal{S}} \pi_s \sum_{t\in\mathcal{T}} \delta_t \left[\sum_{b\in\mathcal{B}_t} \Delta_b \cdot C^{\text{op}}_{s,t,b} + C^{\text{inv}}_t \right] \tag{9}$$

where $\delta_t = (1+r)^{-\tau_t/8760}$ is the discount factor with annual rate r and τ_t the cumulative hours to stage t.

The operational cost for each (s,t,b) is:

$$C^{\text{op}}_{s,t,b} = \sum_{g\in\mathcal{G}} c_g\, p_{g,s,t,b} + \sum_{d\in\mathcal{D}} c^f_d\, q_{d,s,t,b} + \sum_{\ell\in\mathcal{L}} c_\ell (f^+_{\ell,s,t,b} + f^-_{\ell,s,t,b}) \tag{10}$$

The investment cost for stage t is:

$$C^{\text{inv}}_t = \sum_{g\in\mathcal{G}} \omega^{\text{cap}}_{g,t} m_{g,t} + \sum_{d\in\mathcal{D}} \omega^{\text{cap}}_{d,t} m_{d,t} + \sum_{\ell\in\mathcal{L}} \omega^{\text{cap}}_{\ell,t} m_{\ell,t} + \sum_{e\in\mathcal{E}} \omega^{\text{cap}}_{e,t} m_{e,t} \tag{11}$$

where $\omega^{\text{cap}}_{(\cdot),t} = K_{(\cdot)}\delta_t T_t/\sigma$ is the weighted investment cost coefficient, c_g is the variable generation cost [\$/MWh], c^f_d is the demand failure penalty [\$/MWh], c_ℓ is the transmission cost [\$/MWh], $K_{(\cdot)}$ is the annualized investment cost [\$/year] per module for each component, and T_t is the stage duration [h]. All objective coefficients are divided by a scaling factor σ (`scale_objective`, default 1000) to improve solver numerical conditioning. Concretely, each operational LP cost coefficient is weighted by $\omega_{s,t,b} = \pi_s \delta_t \Delta_b/\sigma$, so the reported objective equals z/σ.

D. Bus Power Balance

At every bus n, for each (s,t,b):

$$\sum_{\substack{g\in\mathcal{G}\\ n_g=n}} (1-\lambda_g) p_{g,s,t,b} - \sum_{\substack{d\in\mathcal{D}\\ n_d=n}} (1+\lambda_d)\, \ell_{d,s,t,b} + \sum_{\ell\in\mathcal{L}} A_{n,\ell}\, f_{\ell,s,t,b} = 0 \tag{12}$$

where λ_g, λ_d are injection and withdrawal loss factors, respectively. The line flow terms use directional contributions rather than a simple incidence matrix: for each line ℓ from bus a_ℓ to b_ℓ, the sending bus sees $-f^+_\ell$ (or $+(1-\lambda_\ell)f^-_\ell$ when

losses are modeled) and the receiving bus sees $+(1-\lambda_\ell)f_\ell^+$ (or $-f_\ell^-$), where λ_ℓ is the line loss factor. When $\lambda_\ell = 0$, a single bidirectional variable suffices and the incidence reduces to $A_{n,\ell} \in \{+1, -1, 0\}$. The dual of (12) is the locational marginal price (LMP) at bus n.

E. Demand Balance

When demand curtailment is allowed, served and unserved demand sum to the scheduled load:

$$\ell_{d,s,t,b} + q_{d,s,t,b} = \overline{\ell}_{d,t,b} \quad \forall\, d, s, t, b \tag{13}$$

where $\overline{\ell}_{d,t,b}$ is the scheduled demand at block b, incorporating any demand profile scaling. When curtailment is disabled, the load is fixed: $\ell_{d,s,t,b} = \overline{\ell}_{d,t,b}$.

F. DC Power Flow (Kirchhoff Constraints)

When `use_kirchhoff` is enabled, for each line ℓ and (s, t, b):

$$f_{\ell,s,t,b} = \frac{V_\ell^2}{X_\ell}\left(\theta_{a_\ell,s,t,b} - \theta_{b_\ell,s,t,b}\right) \tag{14}$$

where X_ℓ is the line reactance [Ω] and V_ℓ is the nominal voltage [kV]. A scaling factor σ_θ (`scale_theta`, default 1000) is applied to the angle variables for numerical conditioning: $\theta^{\text{scaled}} = \sigma_\theta \cdot \theta$.

Line flow is bounded by transfer capacities:

$$-\overline{F}_\ell^{ba} \le f_{\ell,s,t,b} \le \overline{F}_\ell^{ab} \tag{15}$$

a) Transmission losses.: When line losses are enabled ($\lambda_\ell > 0$), separate forward and reverse flow variables $f_\ell^+, f_\ell^- \ge 0$ replace the single bidirectional variable. The receiving bus sees only $(1-\lambda_\ell)$ of the dispatched power, so losses are allocated at the receiving end. The Kirchhoff constraint (14) then uses $f_\ell^+ - f_\ell^-$ in place of the single f_ℓ.

b) Transformer model.: For tap-changing and phase-shifting transformers, the Kirchhoff constraint generalizes to:

$$-\theta_{a_\ell} + \theta_{b_\ell} + (\tau_\ell \chi_\ell)(f_\ell^+ - f_\ell^-) = -\sigma_\theta\, \psi_\ell \tag{16}$$

where τ_ℓ is the off-nominal tap ratio (default 1), $\chi_\ell = \sigma_\theta X_\ell / V_\ell^2$ is the scaled reactance, and ψ_ℓ is the phase-shift angle [rad]. When $\tau_\ell = 1$ and $\psi_\ell = 0$, (16) reduces to (14).

G. Battery Energy Storage

State-of-charge balance for battery e between consecutive blocks:

$$\begin{aligned} e_{e,s,t,b} = {} & e_{e,s,t,b-1}(1 - \mu_e^h \Delta_b) \\ & + p^{\text{in}}_{e,s,t,b} \cdot \eta_e^{\text{in}} \cdot \Delta_b - p^{\text{out}}_{e,s,t,b} \cdot \Delta_b / \eta_e^{\text{out}} \end{aligned} \tag{17}$$

where η_e^{in} and η_e^{out} are charge and discharge efficiencies, $p^{\text{in}}, p^{\text{out}}$ are charge and discharge power [MW], and $\mu_e^h = \mu_e/8760$ is the hourly self-discharge rate derived from the annual loss rate μ_e. Initial SoC $e_{e,\cdot,\cdot,0} = e_e^{\text{ini}}$ is an equality constraint in the first stage; the final SoC of stage t links to the initial SoC of stage $t{+}1$.

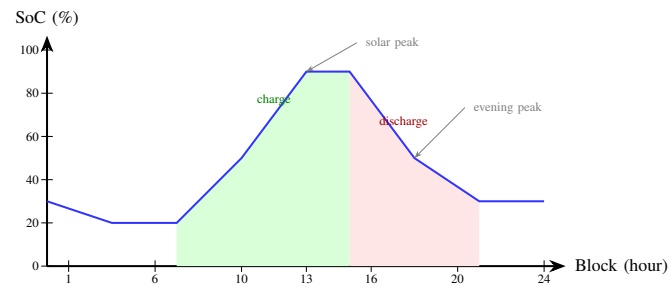

Fig. 2: Battery SoC over 24 blocks: charge during solar hours (green), discharge during evening peak (red).

H. Converter Constraints

A converter v couples a battery e to the electrical network through a generator g (discharge path) and a demand d (charge path) via a power conversion rate ρ_v:

$$p_{g,s,t,b} = \rho_v \cdot p^{\text{out}}_{e,s,t,b} \tag{18}$$

$$\ell_{d,s,t,b} = \rho_v \cdot p^{\text{in}}_{e,s,t,b} \tag{19}$$

When the converter has a capacity limit $\overline{C}_v$, a joint bound applies: $p_{g,s,t,b} + \ell_{d,s,t,b} \le \overline{C}_{v,t}$. Converter capacity is expandable using the same modular framework as (24).

I. Hydro Cascade

For each junction j with reservoir r, the water balance is:

$$\begin{aligned} v_{r,s,t,b} = {} & v_{r,s,t,b-1} \\ & + \alpha_r \Delta_b \Big(\textstyle\sum_{w \in \text{in}(j)} q_w - \sum_{w \in \text{out}(j)} q_w + F_j \Big) \end{aligned} \tag{20}$$

where q_w is the waterway discharge [m^3/s], F_j is the exogenous inflow at junction j, and $\alpha_r = 0.0036$ converts flow rates to volume increments: since 1 m^3/s flowing for 1 hour equals 3600 m^3 = 0.0036 hm^3, we have $\alpha_r = 3.6 \times 10^{-3}$ [hm^3/(m^3/s·h)].

Each turbine h linking waterway w to generator g provides:

$$p_{g,s,t,b} \le \rho_h \cdot q_{w,s,t,b} \tag{21}$$

where ρ_h is the water-to-power conversion rate [MW·s/m^3].

a) Volume-dependent turbine efficiency.: In practice, the conversion rate depends on the hydraulic head, which varies with reservoir volume. When defined, ρ_h is replaced by a concave piecewise-linear function:

$$\rho_h(v) = \min_{i=1}^{N} \{ c_i + m_i (v - v_i) \} \tag{22}$$

where (v_i, m_i, c_i) are volume breakpoints, slopes, and intercepts of N segments. In the SDDP method, the active segment is updated at each forward-pass iteration using the current reservoir volume.

b) Filtration (seepage).: Seepage from a waterway into a reservoir is modeled as a linear function of the average volume:

$$\varphi_{i,s,t,b} = a_i + b_i \cdot \frac{v_{r,s,t,b-1} + v_{r,s,t,b}}{2} \tag{23}$$

where a_i is a constant term and b_i is the seepage rate per unit volume. As with turbine efficiency, this admits a piecewise-linear extension selected by the last known volume.

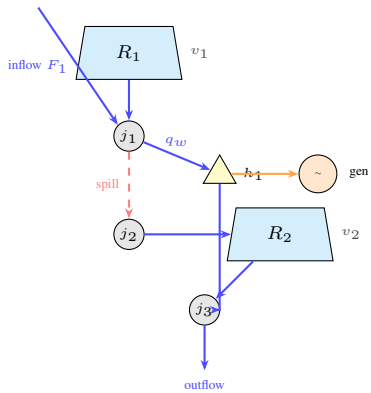

Fig. 3: Hydro cascade example: two reservoirs (R_1, R_2), three junctions (j_1–j_3), one turbine (h_1) driving a generator, with inflow, spillway, and waterway connections.

J. Capacity Expansion

Installed capacity evolves as:

$$\bar{C}_{g,t} = \bar{C}_{g,t-1}(1 - \xi_{g,t}) + M_g \cdot m_{g,t} \tag{24}$$

where $\bar{C}_{g,0}$ is the initial installed capacity, $\xi_{g,t}$ is the stage derating factor, M_g is the capacity per expansion module (`expcap`), and $m_{g,t}$ is the number of modules built. The generator output is bounded by the installed capacity:

$$p_{g,s,t,b} \leq \bar{C}_{g,t} \tag{25}$$

Analogous expansion constraints apply to demands, lines, batteries, and converters.

K. Generator Profile Constraints

When a generator has a capacity profile $\phi_g(s,t,b)$ (e.g., solar irradiance or wind availability), the output is forced to follow the profile:

$$p_{g,s,t,b} + s_{g,s,t,b} = \phi_g(s,t,b) \cdot \bar{C}_{g,t} \tag{26}$$

where $\phi_g(s,t,b) \in [0,1]$ is the per-block capacity factor and $s_{g,s,t,b} \geq 0$ is the curtailed (spilled) generation. The spillover variable carries cost $c_g^{\text{spill}} \cdot \omega_{s,t,b}$, which may be set to zero to allow free curtailment of renewables. This lets the optimizer spill excess renewable production when it is not economically efficient to deliver.

L. Demand Minimum Energy

An optional minimum energy constraint ensures that a demand d is served a minimum total energy within each stage:

$$\sum_{b \in \mathcal{B}_t} \ell^{\text{man}}_{d,s,t,b} \cdot \Delta_b \geq E_d^{\min} \tag{27}$$

where $\ell^{\text{man}}_{d,s,t,b}$ is the mandatory served load and $E_d^{\min}$ [MWh] is the stage energy requirement.

M. Reserve Constraints

For each reserve zone z and (s,t,b):

$$\sum_{p \in \mathcal{P}_z} \gamma_{p,t}\, r^{\text{up}}_{p,s,t,b} + q^{\text{up}}_{z,s,t,b} \geq R^{\text{up}}_{z,s,t,b} \tag{28}$$

where $r^{\text{up}}_{p,s,t,b}$ is the up-reserve provision from provision p, $\gamma_{p,t}$ is the provision factor (typically 1), $q^{\text{up}}_{z,s,t,b}$ is unserved reserve, and $R^{\text{up}}_{z,s,t,b}$ is the zone requirement. A symmetric constraint exists for down-reserve. Reserve provision is bounded by the generator's headroom: $p_{g,s,t,b} + r^{\text{up}}_{p,s,t,b} \leq \bar{C}_{g,t}$.

N. Water Rights and Irrigation Agreements

Hydro-dominated power systems often operate under legally-binding irrigation agreements that partition turbine discharge into distinct rights categories—irrigation, electrical, mixed—with volume-dependent allocations that vary with reservoir level. In Chile, the Laja Agreement (1958, updated 2017) and the Maule Convention (1947) govern two of the largest hydro cascades in the national interconnected system, imposing seasonal flow obligations and multi-annual volume accounting constraints on the optimizer.

Traditional tools such as PLP encode each agreement as a monolithic Fortran module, tightly coupling the rights logic to the physical topology. `gtopt` instead introduces two generic, data-driven entities—*FlowRight* and *VolumeRight*—together with the flexible *UserConstraint* mechanism, forming a *rights-domain* layer parallel to the physical hydro topology. This separation allows arbitrary irrigation agreements to be specified declaratively in JSON and parameterized AMPL-inspired scripts without modifying the solver code.

1) Flow Right: A flow right $i \in \mathcal{FR}$ represents a flow-based water right [m^3/s] that creates one LP column per block. Two operating modes are supported:

- *Fixed mode*: the extraction flow is fixed at a scheduled discharge value $\bar{\xi}_{i,s,t,b}$ (lower bound equals upper bound).
- *Variable mode*: when a maximum flow $\overline{F}_i > 0$ is specified, the optimizer decides the flow $\xi_{i,s,t,b} \in [0, \overline{F}_i]$.

When `consumptive = true`, the flow right subtracts from the physical junction balance, coupling the rights domain to the physical hydro topology. An optional deficit variable with penalty cost c_i^f ensures feasibility when the right cannot be fully served.

A stage-average hourly flow variable $\bar{\xi}_i^h$ is optionally created to aggregate block-level flows into the duration-weighted average required by the volume accumulation equations:

$$\bar{\xi}^h_{i,s,t} = \sum_{b \in \mathcal{B}_t} \frac{\Delta_b}{T_t}\, \xi_{i,s,t,b} \tag{29}$$

2) Volume Right: A volume right $o \in \mathcal{VR}$ is modeled as a virtual reservoir (following the same `StorageLP` pattern as batteries) that tracks accumulated volume [hm^3] across stages. The volume balance is:

$$\nu_{o,s,t} = \nu_{o,s,t-1} - \alpha_o \sum_{b \in \mathcal{B}_t} \Delta_b\, \xi^{\text{in}}_{o,s,t,b} \tag{30}$$

where $\nu_{o,s,t}$ is the remaining volume of right o at the end of stage t, $\xi^{\text{in}}_{o,s,t,b}$ is the input extraction rate [m^3/s], and $\alpha_o = 0.0036$ [hm^3/(m^3/s·h)] is the flow-to-volume conversion factor.

Volume rights support inter-stage state-variable coupling for SDDP, optional demand satisfaction constraints ($\alpha_o \sum_b \Delta_b \xi^{\text{in}}_b + q^{\text{fail}} \geq D_o$), and an automatic seasonal reset mechanism: when a `reset_month` is configured, the accumulated volume is reset to the initial value at the start of each hydrological year.

3) User Constraints and Parameters: The partition logic that links flow rights together—and the proportional allocation rules of the Maule Convention—is expressed through *UserConstraints*: user-defined linear constraints written in an AMPL-inspired pseudo-script. Each constraint is a named linear (in)equality over LP variables of any system element (generators, demands, flow rights, volume rights, etc.) and can optionally restrict its domain to specific scenarios, stages, or blocks.

For the Laja agreement, the total generation flow must equal the sum of all partitioned extraction categories (irrigation, electrical, mixed, and anticipated discharge):

$$\xi^{\text{gen}} = \xi^{\text{irr}} + \xi^{\text{elec}} + \xi^{\text{mix}} + \xi^{\text{antic}} \tag{31}$$

In the `.pampl` template this constraint reads:

```
constraint laja_partition "Flow partition":
  flow_right('laja_total_gen').flow =
      flow_right('laja_irr_rights').flow
    + flow_right('laja_elec_rights').flow
    + flow_right('laja_mixed_rights').flow
    + flow_right('laja_anticipated').flow;
```

This single UserConstraint replaces the hardcoded balance node that traditional tools implement as a dedicated data structure.

For the Maule Convention, the ordinary reserve zone enforces a proportional split between electric (p_e) and irrigation (p_r) extraction from the same shared flow:

$$\xi^{\text{elec}}_{\text{ord}} \leq p_e\left(\xi^{\text{elec}}_{\text{ord}} + \xi^{\text{irr}}_{\text{ord}}\right) \tag{32}$$

$$\xi^{\text{irr}}_{\text{ord}} \leq p_r\left(\xi^{\text{elec}}_{\text{ord}} + \xi^{\text{irr}}_{\text{ord}}\right) \tag{33}$$

where $p_e + p_r = 1$. These two UserConstraints replace the hardcoded Fortran proportional-split logic in PLP's `genpdmaulen.f`.

Named scalar or monthly-indexed *UserParams* (p_e, p_r, cost arrays, seasonal demand curves, etc.) are defined in the same script file and resolved automatically from the stage calendar month, enabling seasonally-varying constraints without per-stage hardcoding. The `plp2gtopt` converter generates these templates automatically from the parsed Fortran agreement parameters.

4) Volume-Dependent Dynamic Bounds: A key feature of irrigation agreements is that the available rights depend on the current reservoir volume. For example, the Laja agreement defines four volume zones that progressively allocate rights as the reservoir fills:

$$\overline{F}_i(V) = \min\Big(c_k + m_k(V - V_k),\ \overline{F}^{\text{cap}}_i\Big) \tag{34}$$

TABLE II: Laja Agreement volume zone allocation factors.

Zone	Width [hm^3]	Irrig. factor	Elec. factor	Mixed factor
Base	—	570	0	30
Zone 1	1 200	0.00	0.05	1.00
Zone 2	170	0.40	0.05	0.00
Zone 3	530	0.40	0.40	0.00
Zone 4	3 682	0.25	0.65	0.00

Base values in m^3/s; zone factors in m^3/s per hm^3. Caps: 5 000 / 1 200 / 30 m^3/s.

TABLE III: Complete constraint summary.

#	Constraint	Eq.	$\forall$
C1	Bus power balance	(12)	n, s, t, b
C2	Demand balance	(13)	d, s, t, b
C3	Kirchhoff voltage law	(14)	ℓ, s, t, b
C4	Generator output bounds	(1)	g, s, t, b
C5	Capacity expansion	(24)	g, t
C6	Generator profile	(26)	g, s, t, b
C7	Demand min. energy	(27)	d, s, t
C8	Line capacity	—	ℓ, s, t, b
C9	Battery SoC	(17)	e, s, t, b
C10	Converter coupling	(18)	v, s, t, b
C11	Reserve requirements	(28)	z, s, t, b
C12	Reserve–generator coupling	—	p, s, t, b
C13	Hydro water balance	(20)	j, s, t, b
C14	Turbine conversion	(21)	h, s, t, b
C15	Transformer / PST	(16)	ℓ, s, t, b
C16	Flow right averaging	(29)	i, s, t
C17	Volume right balance	(30)	o, s, t
C18	User-defined constraint	(31)	user-defined

where (V_k, m_k, c_k) are breakpoints of a piecewise-linear function and V is the current volume of the source reservoir. At each SDDP iteration, the bound is re-evaluated from the forward-pass reservoir volume and applied via `set_col_upp` on the corresponding flow or extraction column.

Table II illustrates the Laja volume zone allocation.

5) Design Advantages: The rights-domain abstraction provides three advantages over the monolithic approach used in traditional tools: (i) new agreements are specified declaratively in JSON and AMPL-inspired scripts without modifying the solver code; (ii) the same two generic entities (FlowRight and VolumeRight) together with UserConstraints express both the Laja and Maule agreements despite their very different structures (4 volume zones vs. 3 reservoir portions, multi-annual vs. seasonal reset, exact partition vs. proportional split); (iii) volume-dependent dynamic bounds integrate naturally with the SDDP forward-pass update mechanism, reusing the same piecewise-linear evaluation used for turbine efficiency. The `plp2gtopt` converter automatically transforms PLP's Fortran agreement parameters into the equivalent `gtopt` JSON configuration and `.pampl` template with verified numerical equivalence.

O. Constraint Summary

Table III lists all constraint families in the formulation.

IV. Solution Methods

`gtopt` implements three complementary solution methods, selectable via the `method` option. All three solve the same underlying GTEP formulation (Section III); they differ in how they decompose the problem across the time and scenario dimensions.

A. Monolithic LP

The default method assembles the entire multi-scenario, multi-stage problem into a single sparse LP/MIP and passes it to the solver backend. The LP is constructed in compressed sparse column (CSC) format via the `FlatLinearProblem` class.

For a system with N buses, G generators, D demands, L lines, E batteries, B blocks per stage, T stages, and S scenarios, the approximate problem size is:

TABLE IV: LP Problem Size Estimates

Quantity	Approximate count
Operational variables	$(G{+}2D{+}2L{+}3E{+}N) \times S \times T \times B$
Investment variables	$(G{+}D{+}L{+}E) \times T$
Bus balance rows	$N \times S \times T \times B$
Kirchhoff rows	$L \times S \times T \times B$ (if DC OPF)
SoC balance rows	$E \times S \times T \times B$
Capacity rows	$(G{+}D{+}L{+}E) \times T$

The monolithic method is exact (no decomposition error) and is recommended for problems where the total number of LP variables fits in memory. For the IEEE 57-bus system with 24 hourly blocks, the LP has approximately $57 \times 24 \times (7 + 84 + 160 + 57) \approx 421\,000$ variables.

B. Stochastic Dual Dynamic Programming (SDDP)

For multi-stage stochastic problems with many scenarios, `gtopt` implements SDDP following the algorithm of Pereira and Pinto [13]. The stages are decomposed into individual subproblems connected by Benders optimality cuts that approximate the expected future cost.

Algorithm 1 SDDP Algorithm in `gtopt`

1: Initialize: empty cut sets $\mathcal{C}_t = \emptyset$ for all t
2: **for** iteration $k = 1, 2, \ldots, K$ **do**
3: **Forward pass**: Solve stages $t = 1, \ldots, T$ sequentially for sampled scenarios; record state variables (SoC, reservoir volumes)
4: **Backward pass**: For $t = T, \ldots, 1$, solve each stage for all aperture scenarios; compute dual variables; generate Benders cuts:

$$\alpha_t \geq \hat{\alpha}_t + \hat{\pi}_t^\top (x_t - \hat{x}_t)$$

5: Add cuts to $\mathcal{C}_t$
6: Check convergence: upper/lower bound gap $\leq \epsilon$
7: **end for**

a) Benders Optimality Cuts.: The core mechanism of SDDP is the Benders optimality cut, which approximates the expected cost-to-go function as a piecewise-linear lower bound. At each backward step for stage t, the cut takes the form:

$$\alpha_t \;\geq\; \hat{z}_{t+1} + \sum_i \hat{\mu}_i \big(x_i - \hat{x}_i\big), \tag{35}$$

where α_t is the future cost variable (the cost-to-go approximation at stage t), $\hat{z}_{t+1}$ is the optimal objective value of the stage-$(t{+}1)$ subproblem evaluated at the trial point, $\hat{\mu}_i$ are the dual multipliers of the state-linking constraints (coupling successive stages through reservoir volumes, state-of-charge, etc.), and $\hat{x}_i$ are the trial state variable values from the forward pass. As iterations proceed, the accumulated cuts progressively tighten the piecewise-linear outer approximation of the true expected cost-to-go, driving the lower bound upward toward the optimum.

b) Cut Coefficient Modes.: `gtopt` supports two modes for computing the cut coefficients $\hat{\mu}_i$ in (35). The `reduced_cost` mode (default) extracts dual information from the reduced costs of the LP solution, which is numerically robust when state variables are at their bounds. The `row_dual` mode instead reads the row dual values of the state-linking constraints directly. Both modes produce valid cuts; the choice can affect convergence speed depending on problem structure and solver backend.

c) Convergence Criterion.: Convergence is checked at the end of each iteration by comparing the upper bound (the average total cost across forward-pass scenario samples) with the lower bound (the optimal objective of the root-stage subproblem, which includes all accumulated cuts). The algorithm terminates when the relative gap satisfies:

$$\frac{z^{\text{upper}} - z^{\text{lower}}}{z^{\text{upper}}} \;\leq\; \varepsilon,$$

where the default tolerance is $\varepsilon = 0.01$ (1%).

The SDDP implementation in `gtopt` includes several enhancements:

- **Apertures**: configurable backward-pass scenario sampling that groups scenarios into subsets for cut generation, reducing computational cost while preserving solution quality.
- **Elastic filters**: infeasible subproblems are handled by relaxing state variable bounds with penalty costs, ensuring the algorithm does not stall.
- **Boundary cuts**: pre-computed future cost approximations at the terminal stage, enabling rolling horizon studies.
- **Hot start**: cuts from previous runs can be loaded to accelerate convergence.
- **Cut management**: dominated cuts are periodically purged to control LP size growth.

C. Cascade Decomposition

The cascade method is a novel multi-level hybrid that decomposes the problem hierarchically:

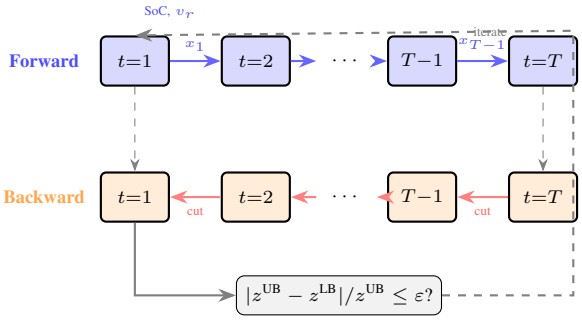

Fig. 4: SDDP forward-backward iteration: the forward pass solves stages sequentially passing state variables (battery SoC, reservoir volume); the backward pass generates Benders cuts. Convergence is checked via the upper/lower bound gap.

1) **Level 0 (strategic)**: A coarsened version of the problem (aggregated blocks, reduced scenarios) is solved monolithically to determine investment decisions and approximate cost-to-go functions.
2) **Level 1 (tactical)**: SDDP is applied to the full stochastic problem using the Level 0 investments as warm-start and the cost-to-go cuts as initial approximations.
3) **Level 2+ (operational)**: Additional refinement levels can solve detailed operational subproblems with fixed investments.

The cascade method inherits SDDP's convergence guarantees while using the monolithic coarse solution to dramatically reduce the number of SDDP iterations required. It is particularly effective for long-horizon problems (10+ stages) with many scenarios.

D. Solver Backend Architecture

All three methods delegate LP/MIP solution to a pluggable solver backend loaded as a shared library at runtime. Currently supported backends are:

- **CLP/CBC** (COIN-OR): Default open-source backend. CLP for LP, CBC for MIP [23].
- **CPLEX** (IBM): Commercial high-performance solver, accessed via the C Callable Library.
- **HiGHS**: Open-source solver with parallel simplex and interior-point methods [24].

The backend is auto-detected by priority (CPLEX > HiGHS > CBC > CLP) or explicitly selected via the `-solver` flag. Solver-specific options (algorithm, threads, tolerances, time limits) are configured through the `solver_options` JSON section.

V. Software Architecture

A. Design Principles

The software architecture of `gtopt` is organized around four core principles:

1) **Performance**: C++26 with flat-map-based sparse matrices for fast LP assembly. The `boost::container::flat_map` (aliased as `gtopt::flat_map`) provides 10–27× faster iteration than `std::map` in LP coefficient assembly.
2) **Modularity**: Each power system component (generator, demand, line, battery, reservoir, etc.) has its own LP assembly class (`*_lp.cpp`) that independently adds variables, constraints, and objective terms to the shared `LinearProblem`.
3) **Extensibility**: New components and solver backends can be added without modifying the core LP engine. Solver backends are loaded as dynamic plugins (`libgtopt_solver_*.so`).
4) **Interoperability**: JSON configuration with native Apache Arrow/Parquet I/O enables seamless integration with Python, R, and other data science ecosystems.

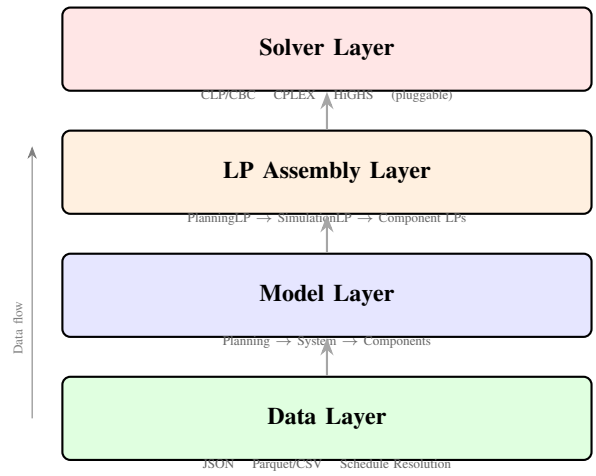

Fig. 5: `gtopt` layered architecture: data ingestion, model construction, LP assembly, and pluggable solver backends.

B. System Architecture

Fig. 5 illustrates the layered architecture.

The software is organized into four layers:

1) **Data Layer**: JSON parsing (via DAW JSON Link, a zero-allocation header-only library), Parquet/CSV I/O (via Apache Arrow C++ SDK), and schedule resolution (`FieldSched<T>` variant type supporting scalar, vector, or filename references).
2) **Model Layer**: The `Planning` → `System` → component hierarchy that maps JSON input to C++ data structures.
3) **LP Assembly Layer**: `PlanningLP` orchestrates `SimulationLP` instances (one per scenario/stage), which in turn assemble component LP objects (`GeneratorLP`, `DemandLP`, `LineLP`, `BatteryLP`, `ReservoirLP`, etc.) into a shared `FlatLinearProblem`.
4) **Solver Layer**: The `SolverBackend` interface abstracts LP/MIP solution. Implementations are loaded as dynamic plugins from configurable search paths.

C. Data Model and JSON Interface

The input is specified as one or more JSON files containing three sections:

```
{
  "options": { ... },
  "simulation": {
    "block_array": [...],
    "stage_array": [...],
    "scenario_array": [...]
  },
  "system": {
    "bus_array": [...],
    "generator_array": [...],
    "demand_array": [...],
    "line_array": [...],
    "battery_array": [...],
    ...
  }
}
```

Listing 1: Top-level JSON structure

Time-series data (demand profiles, generator capacity factors, reservoir inflows) can be specified inline as JSON arrays, or as references to external Parquet or CSV files in the `input_directory`. This hybrid approach keeps the JSON configuration compact while supporting arbitrarily large time-series via columnar Parquet storage.

D. Python Toolchain

A comprehensive Python toolchain (16 registered CLI tools) is provided for data preparation, conversion, and validation:

- **igtopt**: Excel workbook (→ JSON + Parquet) converter for spreadsheet-based case preparation.
- **plp2gtopt**: PLP/PROMAX (→ gtopt) converter for legacy hydrothermal scheduling data.
- **pp2gtopt / gtopt2pp**: pandapower (↔ gtopt) bidirectional converters for power flow model exchange.
- **gtopt_compare**: Automated cross-validation against pandapower DC OPF on IEEE test networks.
- **gtopt_diagram**: Network topology diagram generator using Mermaid syntax.
- **run_gtopt / sddp_monitor**: Execution management and SDDP convergence monitoring.
- **Validation tools**: `gtopt_check_json`, `gtopt_check_lp`, `gtopt_check_output`, `gtopt_check_solvers` for input validation and diagnostics.

E. Web and GUI Services

Two companion services provide graphical interfaces:

- **webservice**: A Next.js REST API and browser UI for submitting optimization jobs, monitoring progress, and browsing results.
- **guiservice**: A Python/Flask application for creating and editing cases through a web-based form interface.

VI. Validation and Benchmark Results

`gtopt` is validated on a comprehensive suite of IEEE benchmark networks and derived cases. All test cases converge to optimal solutions (status 0) with zero optimality gap. Table V summarizes the benchmark suite.

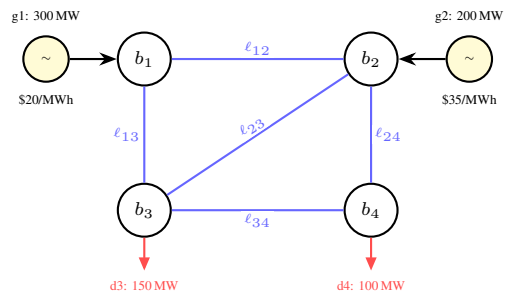

Fig. 6: IEEE 4-bus network: 2 generators, 2 demands, 5 lines forming a fully meshed topology for DC OPF validation.

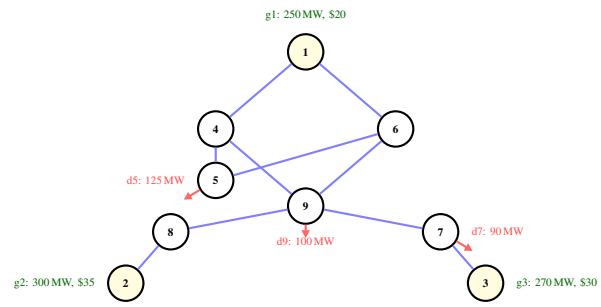

Fig. 7: IEEE 9-bus network: three generation areas (buses 1–3) serve three demands (buses 5, 7, 9) through a meshed 9-line transmission network.

A. IEEE 4-Bus Network

The IEEE 4-bus test case consists of a fully meshed network with 4 buses and 5 transmission lines (Fig. 6). Two generators (g1: 300 MW at $20/MWh, g2: 200 MW at $35/MWh) supply two demands (d3: 150 MW, d4: 100 MW).

Under DC OPF with Kirchhoff constraints, the cheaper generator g1 dispatches 250 MW and g2 idles. The scaled objective value is $5.0 = 250 \times 20/1000$. Power routes through parallel paths (b1→b3 and b1→b2→b3) according to the relative reactances.

B. IEEE 9-Bus Network

The Anderson–Fouad 9-bus system [25] has three generation areas connected by a meshed transmission network (Fig. 7). Generators g1 (250 MW, $20/MWh), g2 (300 MW, $35/MWh), and g3 (270 MW, $30/MWh) serve demands at buses 5, 7, and 9 (total 315 MW).

In the single-snapshot case (`ieee_9b_ori`), economic dispatch follows merit order constrained by network topology. The 24-hour variant (`ieee_9b`) replaces g3 with a solar plant ($0/MWh) whose output follows a daily capacity profile peaking at noon. During daylight hours, zero-cost solar generation displaces g2; at night, g2 carries the load.

C. IEEE 14-Bus Network

The 14-bus system has 5 generators, 11 demands, and 20 transmission lines. The constrained variant (`ieee_14b`) tightens limits on lines ℓ_{1-2} and ℓ_{1-5}, forcing both to saturate simultaneously at the evening demand peak. This validates that

TABLE V: IEEE Benchmark Results (scale_objective = 1000, CLP solver)

Case	Type	Buses	Gen	Dem	Lines	Bat	Obj (scaled)	Blocks
Standard IEEE DC OPF (single snapshot)								
ieee_4b_ori	DC OPF	4	2	2	5	–	5.000	1
ieee_9b_ori	DC OPF	9	3	3	9	–	55.184	1
ieee_14b_ori	DC OPF	14	5	11	20	–	8.334	1
ieee30b	DC OPF	30	6	21	41	–	5.668	1
ieee_57b	DC OPF	57	7	42	80	–	25.016	1
24-hour dispatch with solar profiles								
ieee_9b	Solar+OPF	9	3	3	9	–	5400.007	24
ieee_14b	Solar+OPF	14	5	11	20	–	1492.283	24
Battery energy storage								
bat_4b	BESS+OPF	4	3	2	5	1	14.160	4
bat_4b_24	BESS+OPF	4	3	2	5	1	44.862	24
Capacity expansion								
exp_gen_4b	Gen. exp.	4	2	2	5	–	5.029	4
exp_bat_4b	Bat. exp.	4	3	2	5	1	12.437	4
c0	Dem. exp.	1	1	1	0	–	23.163	5 stages

shadow prices (Lagrange multipliers of the binding Kirchhoff constraints) are computed correctly.

D. IEEE 30-Bus and 57-Bus Networks

The 30-bus [26] and 57-bus [27] systems test scalability. The 30-bus case has 6 generators, 21 demands, and 41 lines; the 57-bus case has 7 generators, 42 demands, and 80 lines. Both converge to optimal solutions in under one second with the CLP solver.

E. Battery Storage Cases

The `bat_4b` case augments the 4-bus network with a 200 MWh battery at bus 3 (60 MW charge/discharge, 95% round-trip efficiency) and a solar generator with a 4-period capacity profile. The battery charges during solar peak and discharges during evening demand, reducing total system cost compared to the no-storage baseline.

The 24-hour variant (`bat_4b_24`) demonstrates full daily charge/discharge cycling with state-of-charge tracking across all 24 blocks.

F. Capacity Expansion Cases

Three expansion cases validate the investment planning formulation:

- `exp_gen_4b`: Generator g1 can be expanded by up to 290 MW at $1000/year annualized cost. The optimizer adds capacity to avoid dispatching expensive g2.
- `exp_bat_4b`: Battery expansion with 200 MWh modules at $1000/year. The optimizer installs storage to arbitrage solar/thermal cost differentials.
- `c0`: Multi-stage demand expansion (5 stages, 10% discount rate). Demand grows through 20 MW modules at $8760/year. The optimizer balances discounted investment cost against increasing served demand.

G. Cross-Validation with pandapower

The `gtopt_compare` tool performs automated cross-validation against pandapower [22] DC OPF on all IEEE test networks (4, 9, 14, 30, 57 buses). For each case, both tools solve the same network data and compare:

- Objective function value (total generation cost)
- Generator dispatch (MW per generator)
- Bus angles (radians)
- Line flows (MW)
- Locational marginal prices (bus balance duals)

Results match to within solver tolerance ($< 10^{-6}$ relative error) for all standard IEEE cases, confirming the correctness of the DC OPF implementation in `gtopt`.

VII. Case Studies

Case studies with real-world applications are planned for a future revision of this paper. The benchmark results in Section VI demonstrate correctness and scalability on standard IEEE test networks; the performance measurements below characterize computational efficiency.

A. Computational Performance

This subsection reports representative performance measurements[1] for LP assembly, solver backends, and SDDP convergence.

1) LP Assembly Performance: Table VI compares the C++ sparse-matrix assembly of `gtopt` (using `std::flat_map` in CSC format) against estimated assembly times for a representative Python toolchain based on Pandas/NumPy patterns (e.g., PyPSA-style modeling).

The C++ sparse-matrix assembly with `std::flat_map` provides a 10–27× speedup over hash-map or Python-based alternatives. The advantage grows for larger problems because the sorted, contiguous memory layout of `flat_map` is cache-friendly: as problem size increases beyond L2 cache capacity,

[1] All timings are representative values measured on an Intel Core i7 workstation with 16 GB RAM running Ubuntu 24.04. Individual results may vary with hardware, compiler, and solver version.

TABLE VI: LP Assembly Time Comparison (Representative)

System	Vars	Constr.	C++	Python*
4-bus, 1 block	∼50	∼30	<1 ms	∼10 ms
14-bus, 24 blocks	∼12k	∼8k	∼5 ms	∼200 ms
57-bus, 24 blocks	∼50k	∼35k	∼20 ms	∼800 ms
57-bus, 8760 blocks	∼18M	∼12M	∼8 s	est. >300 s

*Python estimates based on PyPSA-style Pandas/NumPy assembly patterns.

the penalty for random-access hash-map lookups rises sharply, whereas sequential iteration over a flat container remains efficient. For the largest configuration (57-bus, 8760 blocks), the C++ assembly completes in seconds while the Python estimate exceeds five minutes.

2) Solver Backend Comparison: Table VII shows representative LP solve times for the IEEE 14-bus system with 24 hourly blocks (∼12k variables, ∼8k constraints) across the three supported backends.

TABLE VII: Solver Backend Comparison — IEEE 14-bus, 24 Blocks (Representative)

Backend	LP Solve Time	Status
CLP (COIN-OR)	∼15 ms	Optimal
HiGHS	∼8 ms	Optimal
CPLEX (IBM)	∼5 ms	Optimal

All three backends produce identical optimal objective values (within solver tolerance). CPLEX is the fastest for this problem size, followed by HiGHS; CLP remains competitive and serves as the default open-source backend.

3) SDDP Convergence: For a representative multi-stage stochastic problem—the `c0` test case with 5 stages and 3 scenarios—SDDP converges within 10–15 iterations to within 1% of the monolithic optimum. The final SDDP objective matches the monolithic solution to solver tolerance, validating the equivalence guarantee: because both methods solve the same underlying formulation, the decomposed SDDP solution converges to the global optimum as the cut approximation tightens. This result confirms that the Benders cuts, convergence checking, and cut management logic are correctly implemented.

VIII. Conclusions

A novel, high-performance tool for Generation and Transmission Expansion Planning, designated `gtopt`, has been presented. The main conclusions are as follows:

1) **Complete formulation**: The GTEP problem is formulated as a sparse LP/MIP covering DC optimal power flow with Kirchhoff constraints, battery energy storage with state-of-charge tracking and self-discharge losses, hydro cascade systems with reservoirs, turbines, filtration, and volume-dependent efficiency, a generic water rights layer for irrigation agreement modeling with volume-dependent dynamic bounds, spinning reserve requirements, and multi-stage capacity expansion with annualized investment costs.
2) **Three solution methods**: The monolithic LP provides exact solutions for moderate-size problems. SDDP with multi-scenario apertures handles large stochastic problems efficiently, converging to within 1% of the monolithic optimum in 10–15 iterations. The novel cascade decomposition combines both approaches for long-horizon planning.
3) **High performance**: The C++26 implementation with flat-map-based sparse-matrix assembly achieves a 10–27× speedup over Python-based alternatives in LP assembly. For the largest configuration tested (57-bus, 8760 blocks, ∼18M variables), assembly completes in approximately 8 seconds. Pluggable solver backends (CLP, CBC, CPLEX, HiGHS) are supported through a dynamic plugin architecture.
4) **Validated correctness**: Cross-validation against pandapower DC OPF on IEEE benchmark networks (4–57 buses) demonstrates agreement to solver tolerance ($< 10^{-6}$ relative error). All 13 benchmark cases converge to optimal solutions.
5) **Comprehensive toolchain**: A Python companion toolchain (igtopt, plp2gtopt, pp2gtopt, gtopt_compare) and web interfaces provide a complete workflow from data preparation through result analysis, supporting interoperability with existing planning ecosystems.

A. Future Work

Planned enhancements include:

- **AC OPF support**: Extension of the formulation to include reactive power and voltage magnitude constraints via second-order cone programming (SOCP) relaxations.
- **Unit commitment**: Addition of binary start-up/shut-down decisions and minimum up/down time constraints for thermal generators.
- **Multi-sector coupling**: Extension of the model to include gas networks, district heating, and hydrogen production/storage for integrated energy system planning.
- **GPU-accelerated LP assembly**: Exploitation of GPU parallelism for sparse-matrix construction in very large-scale problems.
- **Machine learning integration**: Application of trained models to warm-start the SDDP algorithm or provide scenario reduction for stochastic programming.
- **Real-world case studies**: Application of `gtopt` to national-scale expansion planning problems with detailed hydro cascade modeling.

The `gtopt` tool is designed to support reproducible research in power system optimization and to facilitate community collaboration in future releases.

Marcelo Matus A. received the Electrical Engineer degree from Pontificia Universidad Católica de Chile and the Ph.D. degree in electrical and computer engineering from the University of Arizona, Tucson, AZ, USA. He is currently a Senior Researcher at Black Bear Engineering SpA and at the Centro Nacional de Inteligencia Artificial (CENIA), Santiago, Chile. He was formerly Subdirector of the Centre for Energy (Centro de Energía), Universidad de Chile. His research interests include power system optimization, mathematical programming, and high-performance computing applied to energy systems. He is the lead developer of gtopt and the FESOP framework.

PLACE PHOTO HERE

María del Pilar Buitrago Villada received the B.Sc. and M.Sc. degrees in electrical engineering from Universidad Nacional de Colombia, Medellín, and the Ph.D. degree in engineering from the same university. Her research focuses on power system expansion planning, renewable energy integration, and optimization under uncertainty. She is a co-developer of the FESOP framework and has contributed to its application in long-term planning of the Colombian and Chilean power systems.

PLACE PHOTO HERE

Erick Sierra Baeza received the Civil Electrical Engineer degree from Universidad de Chile. He is currently with Black Bear Engineering SpA, Santiago, Chile, and affiliated with CENIA. He previously worked at the Centre for Energy, Universidad de Chile. His professional experience spans wind energy integration, capacity expansion planning, hydrological modeling, and development of optimization tools for energy market analysis.

PLACE PHOTO HERE

Carlos Enrique García Bujanda is a Researcher at Black Bear Engineering SpA and affiliated with the Department of Informatics, Universidad de Santiago de Chile. His research interests include power systems optimization, renewable energy integration planning, and development of computational tools for long-term electricity system expansion. He is a co-developer of the FESOP framework.

PLACE PHOTO HERE

Marcos Falcone Salazar received the Electrical Engineer and M.Sc. degrees in electrical engineering from Universidad de Chile and the MBA degree from Universidad Adolfo Ibáñez, Santiago, Chile. He held management positions at Colbún S.A. including Sub-manager of Planning and Development, where he directed an R&D initiative between Colbún, Universidad de Chile, Fondecyt, and CORFO that led to the development of a novel electricity market planning and operation model. He is currently a Professor at the School of Engineering, Universidad Adolfo Ibáñez. His professional interests include power system expansion planning, energy project valuation, and electricity market design.

Gonzalo Bustos Turu received the B.Sc. and M.Sc. degrees in electrical engineering from Universidad de Chile in 2009, the M.Sc. degree in sustainable energy futures from Imperial College London in 2013, and the Ph.D. degree from Imperial College London in 2018, working on smart urban energy systems under the supervision of Prof. Nilay Shah. He is currently a Research Associate at Imperial College London and affiliated with the Centre for Energy, Universidad de Chile. His research interests include urban energy system modeling, demand response, electric vehicle integration, and district-level predictive control.
